Embedding the transverse ligament for the prevention of recurrence in pediatric patients with cubital tunnel syndrome: a retrospective review of 86 cases. Transverse ligament release is the accepted standard for treatment of pediatric cubital tunnel syndrome (CTS). The conventional transverse ligament release, however, may expose the ulnar nerve and the posterior interosseous nerve, resulting in recurrent symptoms and recurrence. To prevent nerve injury during transverse ligament release, we used a modified technique of transverse ligament release with or without subcutaneous anchor. The present study retrospectively reviewed 86 patients who underwent transverse ligament release (43 from 2008 and 43 from 2010) to determine the effectiveness of subcutaneous anchor as a novel technique for the prevention of nerve injury in pediatric patients with CTS. All patients showed complete resolution of their symptoms. No postoperative ulnar nerve problems or recurrence were noted during the follow-up period. We modified the conventional transverse ligament release technique by placing an anchor to the subcutaneous tissue over the ulnar head and gradually inserting the transverse ligament to the ulnar head. In the patients who underwent transverse ligament release alone, the percentage of patients who exhibited a positive Phalen test improved from 25.5% before surgery to 89.3% after surgery (P 0.05) and the percentage of patients who exhibited positive Tinell's sign improved from 0% before surgery to 90.2% after surgery (P 82157476af
